The origin of spectral analysis: the analysis of mineral waters. In Europe health spas and community baths have been fashionable for centuries, tracing back to Roman times (Figure 1). We have seen in a previous HEXAGON article that Paracelsus visited several mineral baths—including Bad Pfäfers and Bad Liebenzell (see map, Figure 2)—and wrote reports on their healing powers.2 When Joseph Priestley reported in 1767 that he had synthesized a synthetic carbonated water in Leeds, England, (proposing it as a cure for scurvy),2 he called it "artificial Pyrmont water" after the famous springs at Bad Pyrmont, Germany (Figure 3). Another well-known Kurzentrum (health resort) in Germany was Bad Durkheim (Figure 4), whose water was analyzed in 1861 by chemist Robert Bunsen (1811-1899) and physicist Gustav Robert Kirchhoff (1824-1887). Using their newly-founded science of spectral analysis at the nearby University of Heidelberg, they discovered two new elements, cesium and rubidium, in the Bad Durkheim waters.23 These were the first elements to be discovered spectroscopically.

Today as one enters the Altstadt (Old City) of Heidelberg, one is greeted by a towering statue of Bunsen (Figure 5). Directly across the street stands the medieval building where spectroscopy was born (Figure 6). In spite of the assertion of August Comte (1798-1857) that mankind would "never know anything of the chemical nature of planets and the stars,"4 upon their invention of the spectroscope in 1859 Bunsen and Kirchhoff quickly identified half a dozen elements in the sun.

"Bunsen's greatest discovery: Kirchhoff."5a

While still a graduate student at the University of Königsberg (1842-1847), Kirchhoff had formulated the laws of circuitry which have been in use in electrical engineering for over a century and a half. He accepted a position at the University of Breslau (1850-1854; now Wroclaw, Poland) where he met Bunsen.5b He followed Bunsen to Heidelberg where the two initiated their successful collaborative work.5b Thereafter Kirchhoff moved on to the University of Berlin in 1875 to accept a chair of theoretical physics.6

Kirchhoff is celebrated for his Three Laws of Spectroscopy6 (1859-1962) which he formulated in Heidelberg. In these laws he differentiat-
ed (a) black-body radiation (a term he coined); (b) emission spectra, where bright lines are produced by hot gases; and (c) absorption spectra, where dark lines are observed in continuous spectra when light passes through a cooler gas. His black-body concept had far-reaching consequences, leading eventually to Planck’s quantum theory. His understanding that the bright lines of emission spectra and the dark lines of absorption spectra were identical wavelengths (signaling the same respective elements either “hot” or “cold”) allowed him to explain the puzzling Fraunhofer lines, the dark lines in the solar spectrum first described in 1814 by Joseph von Fraunhofer (1787–1826).

It had been known for a century that different elements can be distinguished by different flame tests, i.e., they glow different colors when heated in a flame. Marggraf used this technique in 1758, for example, to distinguish sodium and potassium. Bunsen chose this principle to analyze elements, and he used colored glass to distinguish subtle color differences, such as that between lithium and strontium, both of which give red flame tests. Kirchhoff suggested the use of a prism, which would separate the colors sharply. John Herschel in 1822 had shown that heating chlorides of strontium, calcium, barium, copper, and boric acid gave unique bright lines and Henry Fox Talbot distinguished lithium and strontium by passing light through a prism, but it was the team of Bunsen and Kirchhoff who combined all previous techniques and principles into one device.

The invention of the spectroscope created a sensation in the scientific world, and Bunsen’s “flame reaction” techniques soon replaced blowpipe analysis (pioneered by the Swedes) which had previously been the fashionable and handy way to identify elements in mineral analysis. The more sensitive and higher resolution method of spectroscopic analysis which was used to discover cesium and rubidium soon led to the discovery of many new elements by other investigators, including thallium, indium, gallium, helium, and several rare earths.

The discovery of cesium and rubidium. When Bunsen turned his newly-invented spectroscope to the analysis of Dürkheim mineral waters, he found new spectral lines which announced the presence of cesium (blue line) and rubidium (red line). He concentrated 40 tons of mineral water to obtain weighable amounts of crude salt for chemical tests, although the original detection could be accomplished with only a minute amount of water because of the extreme sensitivity of the spectroscopic method. The original spectral analysis of Dürkheim waters prominently displayed the lines of cesium, but only with much effort were faint lines seen attributable to rubidium. Other spars signaled the presence of cesium, including Wiesbaden and Baden-Baden, but rubidium was more elusive. A better source for rubidium was lepidolite (a lavender form of mica), principally from “Rozena in Mähr” (Moravia), today known by the Czech name Rozná, from a pegmatite ootropping on the outskirts of town (N 49° 28.82 E 16° 15.50). Lepidolite not only furnished weighable amounts of rubidium salts, but purer samples, because cesium was absent in this mineral. Lepidolite has the typical formula KLi₂AlSi₄O₁₀F₂ with substitution of potassium by rubidium approaching 4% in extreme cases. Bunsen observed 0.2 wt. % rubidium, corresponding to a substitution rate of K by Rb of about 1%. Bunsen was able to prepare metallic rubidium by using the “common procedure” of the mid-1800s to procure quantities of potassium: heating a mixture of charcoal and the alkali tetrarate (or carbonate) to redness in an iron retort to yield carbon monoxide and the metal which was distilled directly into oil to avoid reaction with oxygen or moisture. In spite of these forcing and crude reaction conditions, Bunsen incredibly was able to procure a sample of rubidium which was...
pure enough to give an accurate melting point of 38.5° (today’s value, 38.89°). The more electropositive cesium would not yield to this procedure; only an amalgam could be prepared. The preparation of pure cesium had to wait another 20 years, when in the same laboratory of Bunsen the more refined procedure of electrolysis was successful, using cesium cyanide. Modern methods of producing both metallic rubidium and cesium involve electrolysis techniques.

The first mineral in which cesium was observed was pollucite (a zeolite) from La Speranza quarry, San Piero in Campo, Elba Island, Italy (N 42° 44.83 E 10° 12.55); these deposits have since been depleted. Fifteen years before Bunsen’s work, a sample of Elba pollucite had been analyzed by Carl Friedrich Beringer (1801–1888) who was puzzled by its
for the flame source of the spectroscopy of Bunsen and Kirchhoff.

The exhibit at the New Campus. In the Horsaal of the Chemistry Department at the New Campus, 2 km to the west of the Altstadt (see map, Figure 2), stands a long parade of display cases (Figure 8) which hold the history of Bunsen and Kirchhoff's work at the University of Heidelberg. The original spectroscopy (Figure 9) and Bunsen burner (Figure 10) are presented. Original preparations of rubidium and cesium are shown (Figure 11). Other showcases include his chromic acid battery (he found chromic acid was better than nitric acid for an electrolyte), other instruments used in his laboratory, chemical preparations, historic letters, and even his death mask. At the end of the hallway is a life-size enlargement of the famous photograph of Kirchhoff, Bunsen, and Roscoe (Figure 12). Roscoe moved in 1857 to Owens College in Manchester, England, where he gained fame with his research on vanadium compounds: he was the first to isolate the element in metallic form (Note 1). Roscoe and Bunsen remained close friends throughout their lives.

The legacy of Bunsen. Bunsen was a modest man. His "manners were simple but dignified, and his expression one of rare intelligence and great kindness." He was quiet and helpful, always in the laboratory with his students, making sure that the beginners were helped and encouraged as well as the experienced. Once when praised for his honors and awards, he said, "These things were valuable only because they pleased my mother, but she is no longer alive." He is reported never to have used the word "I" ("ich") when referring to his work; instead, he always said, "Man hat gefunden..." ("It has been observed..."). To others for their discoveries, however, he always gave full credit.

Bunsen was solely occupied with experimentation and facts and resisted being drawn into theories: "One irrefragable and important act was worth an ocean of theories." In his last lectures of 1889, he did not even refer to the Periodic Law of Dmitri Mendeleev and Lothar Meyer, both of whom had worked with him in Heidelberg.

In spite of his modesty, the name "Bunsen" is probably more familiar to the layman or begin-
ning student than any other 19th century chemist, because of the eponymous burner. After its invention, it soon became the standard heating device in all laboratories. Beatrix Potter, the niece of Sir Henry Roscoe, has prepared a fitting tribute to the fame and historic charm of the Bunsen burner (Figure 13, the cover of this issue; and the accompanying article, page 47).

Notes.

Note 1. Sir Henry Enfield Roscoe (1824–1887) studied at the University College, London (1848–1853) and then with Bunsen at the University of Heidelberg (1855–1856). He succeeded Edward Frankland (1825–1899, noted for his introduction of the theory of valence) at Owens College in Manchester in 1857. The building comprising Owens College still stands (19 Quay Street, N 53°28.72 W 02°15.12). For several years Roscoe would return to Heidelberg during the summers to continue collaboration with Bunsen.

His most noted work at Owens College was the first preparation of metallic vanadium in 1869 and the recognition of the many oxidation states (with associated vivid colors) of that element. His dedication to society was exemplified by his service to the unemployed textile workers of Manchester during the early 1860s during the blockade of America’s cotton throughout the War Between the States. Roscoe wrote an interesting autobiography which conveys a realistic portrayal of the times in which he lived. Many of his chemical samples may be viewed in the archives of the Museum of Science and Industry (as well as exhibits on John Dalton), Liverpool Road, Castlefield (a SW suburb of Manchester), N 53°28.63 W 02°15.25. The Roscoe Building (Brunswick St., N 53°28.02 W 02°13.89) at the modern University of Manchester is named for him. ◇

March 28, 2008

Dear Jim and Virginia,

I enjoyed reading your article about Yttrium and Johan Gadolin in the spring issue of Hexagon. Thanks, it was well done.

The photographs and maps provide a good connection with the reality of the times. I suppose they came from Professor Pekko Pyykkö in Helsinki.

I am an organic chemist and missed getting much background on the rare earths. I joined the Alpha Phi Chapter of Alpha Chi Sigma when I was a grad student at the University of Tennessee in Knoxville in 1947.
